• Background and Aims Along snowmelt gradients, the canopies of temperate alpine meadows differ strongly in their structural and biochemical properties. Here, a study is made of the effects of these canopy dissimilarities combined with the snow-induced changes in length of growing season on seasonal gross primary production (GPP).
• Methods Leaf area index (LAI) and community-aggregated values of leaf angle and leaf nitrogen content were estimated for seven alpine plant canopies distributed along a marked snowmelt gradient, and these were used as input variables in a sun–shade canopy bulk-photosynthesis model. The model was validated for plant communities of early and late snowmelt sites by measuring the instantaneous CO$_2$ fluxes with a canopy closed-chamber technique. A sensitivity analysis was conducted to estimate the relative impact of canopy properties and environmental factors on the daily and seasonal GPP.
• Key Results Carbon uptake was primarily related to the LAI and total canopy nitrogen content, but not to the leaf angle. For a given level of photosynthetically active radiation, CO$_2$ assimilation was higher under overcast conditions. Sensitivity analysis revealed that increase of the length of the growing season had a higher effect on the seasonal GPP than a similar increase of any other factor. It was also found that the observed greater nitrogen content and larger LAI of canopies in late-snowmelt sites largely compensated for the negative impact of the reduced growing season.
• Conclusions The results emphasize the primary importance of snow-induced changes in length of growing season on carbon uptake in alpine temperate meadows. It was also demonstrated how using leaf-trait values of the dominants is a useful approach for modelling ecosystem carbon-cycle-related processes, particularly when continuous measurements of CO$_2$ fluxes are technically difficult. The study thus represents an important step in addressing the challenge of using a plant functional-trait approach for biogeochemical modelling.

Key words: Alpine meadows, gross primary production, plant functional traits, snowmelt gradient, sun–shade model.

INTRODUCTION

The carbon budget of cold, snow-covered ecosystems is of particular interest because they are known to sequester a large amount of organic carbon in their soils and to be particularly sensitive to global warming (Hobbs et al., 2000). Much attention has been drawn to the carbon balance of arctic tundra (Vourlitis et al., 2000; Grant et al., 2003; Campbell et al., 2005; Euskirchen et al., 2006), but carbon balance estimations for temperate alpine tundra and meadows are relatively uncommon (Cernusca, 1989; Diemer, 1994). In cold ecosytems, snow determines the length of the season, which is a main driver of carbon exchange between land and atmosphere (Arora and Boer, 2005; Churkina et al., 2005). Recent climatic studies have highlighted the impact of rising temperatures on snow-cover depth and duration at high elevations (Keller et al., 2005), but their consequences for the carbon budget remain poorly understood (Brooks et al., 1997; Monson et al., 2006).

In situ continuous recording of CO$_2$ fluxes remains difficult in high-elevation terrains (but see Cernusca et al., 1998; Li et al., 2005; Hammerle et al., 2007). The alpine landscape generally exhibits very fine-scale changes in vegetation cover, a feature that would preclude the designation of turbulent fluxes to a particular ecosystem. For the same reason, remote-sensing-based estimates of gross primary production (GPP) in alpine landscapes also suffer from insufficient spatial resolution (Turner et al., 2004). This makes spatial and temporal scaling-up a major challenge. A growing body of literature suggests using plant functional traits in ecosystem modelling in order to scale-up ecosystem processes on a mechanistic basis (Diaz and Cabido, 2001; Lavorel and Garnier, 2002). Although this approach has recently been used in modelling primary productivity and litter decomposition (Quetier et al., 2007), to our knowledge, this promising avenue has seldom been explored to model seasonal variations in GPP of herbaceous ecosystems.

According to the ‘biomass ratio hypothesis’ (Grime, 1998), ecosystem properties and function (i.e. carbon and nitrogen cycles) should be related to the trait values of the dominant contributors to the plant biomass. Several key ecosystem processes, such as decomposition rate or productivity, may be predicted from the traits of the dominant species (Chapin et al., 1996; Cornelissen et al., 1999; Epstein et al., 2001). A main challenge is to mechanistically link ecosystem processes to a set of key plant
functional traits that could easily be measured in the field (Diaz and Cabido, 2001). In this respect, it has been proposed that the use of quantitative traits would be more powerful than a broad categorization into discrete plant functional groups (Garnier et al., 2004). The mean of trait values weighted by the relative abundance of each species – i.e. a community-aggregated value (Violle et al., 2007) – provides a route to scale-up from organ to community level and offers a linkage between comparative plant ecology and ecosystem modelling. The goal of this paper is to develop such a modelling approach to estimate the seasonal GPP of temperate alpine meadows. Gross primary production is a key variable of the carbon balance as it quantifies the amount of autotrophic carbon available for growth, reserve and respiratory demands at the ecosystem level.

In alpine ecosystems, the landscape-scale distribution of snow (which is tightly related to the mesotopography) is a main driver of ecosystem structure and functioning. Through its effect on the length of the growing season, snow provides a complex ecological gradient affecting the seasonal course of temperature, light, wind exposure, soil water content and nitrogen availability (Jones et al., 2000). It has long been known that arctic and temperate alpine plant communities exhibit high species turnover along snowmelt gradients (e.g. Komarkova and Webber, 1978; Kudo and Ito, 1992; Onipchenko and Blinnikov, 1994; Theurillat et al., 1994). More recent studies have indicated that consistent shifts in plant functional diversity occur from early to late-snowmelt sites (Kudo et al., 1999; Choler, 2005). A greater leaf nitrogen concentration (N\text{mass}), a higher specific leaf area (SLA) and a predominance of horizontal leaves (i.e. trait values generally associated with a high capacity for resource acquisition) are common features of species from snowy sites (Choler, 2005). Conversely, species from early melting sites are characterized by upright and thick leaves and low SLA, i.e. trait values generally associated with nutrient-conservation strategies (Wright et al., 2004).

Many studies have investigated the relationships among several canopy properties – leaf area index (LAI), nitrogen content, canopy architecture – and their effect on carbon uptake in different light conditions (Anten et al., 1995; Hikosaka and Hirose, 1997; Anten, 2005). But, to our knowledge, there has been no attempt to examine these relationships for multispecies assemblages distributed along gradients of length of growing season. In this study, we addressed the following questions. (1) What are the differences in the community-aggregated values of leaf functional traits along the snow-cover gradient? (2) What is the relative effect of these canopy functional properties and environmental factors (light and temperature regime, length of growing season) on the seasonal GPP? (3) To what extent do plant communities from late-snowmelt sites overcome the negative impact of a reduced growing season on GPP?

This study was based on previous work investigating changes in plant functional traits at the species level along snowmelt gradients in the alpine zone of the southwestern Alps (Choler, 2005). For this work, a sun–shade canopy bulk-photosynthesis model was implemented to simulate the light interception and the GPP at the ecosystem level. The model was validated with instantaneous measurements of CO\textsubscript{2} fluxes using a closed-chamber technique. Finally, a sensitivity analysis was conducted in order to determine the relative effects of climatic factors and canopy functional properties on the seasonal GPP.

MATERIALS AND METHODS

Study site and plant trait measurements

The research site was located in the south-western Alps (France) between the Lautaret and Galibier Pass (45°7′N, 6°5′E). The 2-ha site is a slightly inclined depression located between 2700 and 2780 m a.s.l. It exhibits a typical mosaic of alpine meadow species, ranging from Kobresia myosuroides-dominated plant communities in the early snowmelt sites to Carex foetida- and Alchemilla pentaphyllea-dominated plant communities in the late-snowmelt sites. For this work, the seven plant communities that are the most abundant in the studied area were selected. The communities are designated here according to the mean date of snowmelt in Julian days (e.g. C130, C140, C150, etc). Leaf angle, specific leaf area and leaf nitrogen concentration [expressed on a mass (N\text{mass}) or area (N\text{area}) basis] were used in this study because of their known effect on carbon-cycle-related processes. Further details of the site and trait measurements are given in Choler (2005).

For each trait, a community-aggregated value (T\textsubscript{i}) was calculated as follows:

\[ T_i = \sum_{i=1}^{n} p_i \cdot t_i \]

where \( p_i \) is the relative cover of species \( i \) in the sampling unit (SU), \( n \) is the number of species accounting for 80 \% of the cover in the SU, and \( t_i \) is the trait value of species \( i \). Although the total coverage of the \( n \) species could slightly exceed 80 \%, we did not correct the community-aggregated value. In practical terms, the change in \( T_i \) value because of this discrepancy is of very limited magnitude (Cornelissen et al., 2003).

For each plant community, the peak standing biomass was harvested at the end of July in square plots of 50 × 50 cm. To calculate the leaf area index (LAI), the whole projected surface of green biomass for three harvests per community was measured using a leaf area meter (WinDIAS, Delta-T Devices Ltd). Separation between green and dead phytoelements was hard to achieve in early snowmelt sites, and hence LAI might have been slightly over-estimated for these communities. Material was then dried at 85 °C for 48 h and weighed.

Climate

Hourly soil temperatures were recorded using Hobo probes (Onset Computer Corporation, Bourne, MA)
buried at 5-cm depth over the period 1999–2005. During snow-covered periods, soil temperatures were close to 0 °C (usually between −1 and 1 °C) throughout the day and did not exhibit circadian variations, a recording consistent with a continuous snow cover of at least 1 m depth. The length of the growing season was calculated as the number of snow-free days with a mean soil temperature above 0 °C.

During the summer season, air temperature, relative humidity and photosynthetically active radiation (PAR) were recorded hourly by an automatic weather station [Campbell Scientific (Canada) Corp.] located in the Jardin Alpin du Lautaret (2100 m a.s.l.), 5 km from the study site. The diffuse and direct components of PAR were calculated according to Spitters (1986). Daily integrated values of incoming solar radiation were obtained from a longer time series (1999–2004) at Briançon climatic station (1300 m a.s.l.), located at 30 km from the site and maintained by Météo France.

The Clear Sky Model (CSM) developed in the framework of the European Solar Radiation Atlas (Rigollier et al., 1999) was used to model the incoming global irradiance on a horizontal plane under a cloudless sky. In the CSM, the direct (or beam) radiation (I_{0b}) and the diffuse radiation (I_{0d}) are simulated separately. Details of the CSM can be found in Rigollier et al. (1999). Solar geometry was implemented using equations written by L. Wald and O. Bauer (École des mines de Paris, Centre d’Énergétique, Groupe de Télédétection, February, 1997). The model was implemented with no mask effect due to the relief. The long-term recordings of daily irradiance in Briançon were used to parameterize the monthly mean atmospheric turbidity in the area.

**Canopy bulk-photosynthesis model and simulation of seasonal GPP**

We developed a modified version of the sun–shade model of De Pury and Farquhar (1997) to estimate the canopy-intercepted radiation and CO₂ fixation. For light interception, the model splits the canopy into a sunlit and a shaded fraction, which experience distinct light regimes. Shaded leaves receive scattered light and diffuse sky irradiance while sunlit leaves receive direct-beam irradiance in addition to this. CO₂ fixation is based on the von Caemmerer and Farquhar biochemical model of C₃ leaf CO₂ assimilation (Farquhar et al., 1980; von Caemmerer and Farquhar, 1981). Below, we only detail the main changes made to the original sun–shade model. The main constants, parameters and equations of the model are given in the Supplementary Information, available online.

(1) We used the ellipsoidal distribution model (Campbell, 1990) to describe the leaf-inclination distribution (or leaf eccentricity) in the canopy. For simplicity, the canopy is considered as spatially homogeneous, i.e. with no clumped leaves in either the vertical or horizontal dimensions. The model assumes that the leaf-angle distribution is similar to the distribution of area on the surface of an ellipsoid. The model requires only one parameter (ε), which is the ratio of the axes of the ellipsoid. The leaf-azimuth-angle distribution is assumed to be uniform; as such, the leaf-inclination probability density function g will solely depend on zₜ, the zenith angle of the leaf normal (see Supplementary Information, Table S2, eqn 1, available online). We estimated the parameter ε from community-aggregated values of leaf angle (Table S2, eqn 2). The use of the ellipsoidal distribution model modifies the calculations of the canopy extinction coefficient for direct radiation (kₒ) as well as the canopy reflection coefficient (Table S2, eqns 4–6).

(2) The Rubisco capacity is linearly related to the leaf nitrogen content. The mean slope of the N_{area}–V_{c,max} relationship (the parameter s₀) was derived from ACᵢ response curves of six alpine species (see Supplementary Information online) and from published data for 13 other species (Wohlfahrt et al., 1998). The minimum leaf nitrogen content, N_{min}, corresponds to the x-intercept of the N_{area}–V_{c,max} linear relationship. Much attention has been devoted to the vertical distribution of nitrogen in models of canopy photosynthesis (Friend, 2001). Under non-uniform distribution of nitrogen within the canopy, V_{c,max} is also a function of canopy depth (Table S2, eqn 12). Following Schieving et al. (1992), we used generalized circle equations to model, with a single parameter p_s, different curvatures in the profile of the nitrogen distribution within the canopy while keeping the total amount of nitrogen, N_{tot}, constant (Table S2, eqn 13). If p_s = 1, N_{area} decreases linearly with canopy depth, while a uniform distribution is achieved when p_s tends towards infinity. Our preliminary measurements did not support non-uniform nitrogen distribution in early and late-snowmelt alpine meadows. Nevertheless, we maintained this model parameterization in order to compare the potential impact of nitrogen distribution with other factors.

(3) The photosynthesis model was combined with a model of stomatal conductance using the empirical approach developed by Ball et al. (1987; Table S2, eqns 24–28, online). Lack of data for accurate parameterization required that several simplifications had to be made. First, we used the relative humidity of ambient air as a surrogate for the leaf surface water vapour pressure. Secondly, boundary layer conductance to H₂O was set constant. Due to the interdependence of leaf net photosynthesis and stomatal conductance, we used an iteration method to calculate Cᵢ (Harley and Tenhunen, 1991). Parameters for the stomatal conductance sub-model were taken from the work of Wohlfahrt et al. (1998).

(4) Seasonal GPP was estimated by running the canopy bulk-photosynthesis model from 10 May to 20 August. This 100-d period was divided into ten sub-periods of 10 d. For each sub-period, we calculated on an hourly basis the daily time course of air temperature, light and relative humidity for sunny, cloudy and intermediate days. Each sub-period comprised six sunny days, two cloudy days and two intermediate
days. These relative contributions were derived from an analysis of the long-term recordings of daily irradiance in Briançon (see ‘Climate’, above). The seasonal evolution of LAI was described as a linear function of cumulative degree days (DD) after snowmelt, as follows:

$$\text{LAI}(t) = \text{LAI}_{\text{max}} \times \frac{\text{DD}(t)}{\text{DD}(t_{\text{opt}})}$$

where $\text{LAI}_{\text{max}}$ is the measured LAI at the time of peak standing biomass ($t_{\text{opt}}$). This parameterization allows the capture of the faster initial development of canopies from late-snowmelt sites.

To assess the relative importance of canopy functional properties and climatic factors on carbon uptake, we conducted sensitivity analyses by systematically varying one factor, i.e. a model parameter or a variable, while keeping the other factors constant and calculating the relative effect on the seasonal GPP.

Model validation by canopy gas-exchange measurements

A closed system was used to measure the CO$_2$ exchange of alpine meadow monoliths taken from an early and a late-snowmelt site (communities C140 and C180, respectively). Early snowmelt monoliths were sampled in the vicinity of the site of where plant trait measurements were taken. But for practical reasons, late-snowmelt monoliths were sampled near the Agnel Pass at 2760 m a.s.l., located in the Queyras mountain range. For each community, five monoliths of 20-cm depth and 50 × 25 cm area were excavated during autumn 2005, and brought to the laboratory. This indicated that the monoliths recovered well from excavation.

For CO$_2$ flux measurements, a 48-L Perspex chamber was placed over each monolith and sealed around the base by seating it in a trough of water. Within the chamber, a fan (Radio Spare) provided air mixing above the canopy. The chamber was connected to a portable IRGA (EGM-4, PPSystems, Hitchin, UK) measuring the CO$_2$ concentration every minute. The rate of change of CO$_2$ in the chamber was determined by averaging the measurements under steady-state conditions, which typically began after 1 min. The measurement periods were generally brief, not exceeding 3 min in order to minimize chamber effects. We simultaneously recorded photosynthetically active radiation (PAR), air and soil temperature, and relative humidity (RH) within the chamber. The rate of change in chamber CO$_2$ concentration was converted into a CO$_2$ exchange rate per ground area. Net CO$_2$ fluxes under light conditions ($F_n$) were collected on both cloudy and sunny days in mid-July, 2006. Dark respiration rates ($R_d$) were measured before and after the light treatment by placing a dark cover over the chamber. There was no indication that respiration increased after the light treatment. Instantaneous rates of gross CO$_2$ uptake (GPP) were calculated as $GPP = F_n + R_d$. LAI and $N_{\text{tot}}$ were measured on three 5 × 5 cm square plots per monolith. The mean LAI of early snowmelt monoliths was 1.3, and the mean $N_{\text{tot}}$ was $208 \text{ mmol N m}^{-2}$. The mean LAI of late-snowmelt monoliths was 2.2, and the mean $N_{\text{tot}}$ was $280 \text{ mmol N m}^{-2}$.

Model performance was evaluated quantitatively by calculating the square of Pearson’s correlation coefficient ($r^2$), and qualitatively by the root-mean-square error (RMSE) and the mean absolute error (MAE), summarizing the mean differences between observed and predicted values (Willmott and Matsuura, 2005).

Numerical simulations, statistical analyses and graphics were performed with the R software environment (R Development Core Team, 2006). The source code is available upon request.

RESULTS

Climatic conditions along the snowmelt gradient

The yearly course of soil temperature for the early (C140) and the late (C180) snowmelt sites is depicted on Fig. 1. The delayed onset of growing season, by nearly 40 d, is constant throughout the 7 years of recordings (Fig. 1A). This difference accounts for a loss of around 280 °Cd at the early snowmelt site at the time of peak standing biomass, which is 30 % fewer degree-days than at the early snowmelt site (Fig. 1B). By comparison, inter-annual variability in cumulative degree-days in the snowy sites is about an order of magnitude below that of the early snowmelt sites (Fig. 1B).

The annual cycle of incident solar radiation measured during cloudless days is fitted well by the clear sky model (Fig. 2A). Around 60 % of days during the growing season received more than 70 % clear-sky radiation, hereafter referred to as ‘sunny days’. Thus, cloudless weather conditions predominate in this area of the southwestern Alps. The effect of cloudiness accounts for a 10 % reduction in total radiation received by the early snowmelt sites compared to the clear sky model (Fig. 2B). Later snowmelt in C180 is responsible for a 40 % reduction in the cumulative incoming solar radiation over the growing season when compared with early snowmelt sites, i.e. from 0.22 MJ cm$^{-2}$ to 0.13 MJ cm$^{-2}$ (Fig. 2B). Inter-annual variations are small compared with those attributable to the timing of snowmelt (Fig. 2B). The daily time course of climatic data for the three types of day is given in the Supplementary Information (Fig. S1, available online).

Plant functional traits along the snowmelt gradient

Graminoids, erect forbs and large leafy rosettes are the main plant life forms accounting for up to 80 % of the vegetation cover in the study area (Table 1). Early snowmelt sites exhibit a discontinuous vegetation cover and a high proportion of bunch graminoids (e.g. Kobresia myosuroides), whereas tiny erect forbs and stoloniferous graminoids are predominant at the snowy sites. The snowmelt
gradient was also characterized by a marked shift in community-aggregated values of leaf traits, with planophilius canopies with a high $N_{\text{mass}}$ and high SLA at the snowy sites, and erectophilous canopies with low SLA and high $N_{\text{area}}$ at the early snowmelt sites (Fig. 3).

Canopies of late-snowmelt sites exhibited larger LAI and greater $N_{\text{tot}}$ (Table 1). It should be stressed that the range of variation for LAI (from less than 1.0 at the early snowmelt sites to around 2.5 at the mid-part of the gradient) largely exceeded that of $N_{\text{area}}$. Therefore, the total nitrogen pool in the canopy, $N_{\text{tot}} = \text{LAI} \times N_{\text{area}}$, is primarily determined by LAI, and to a lesser extent by $N_{\text{area}}$.

Daily and seasonal gross primary production

Modelled values of instantaneous gross CO$_2$ uptake corresponded well with measurements under cloudless and overcast conditions, although there was a slight overestimation for early snowmelt canopies (Fig. 4). Increased carbon fixation under conditions of high diffuse radiation was particularly noteworthy for canopies with high LAI (Fig. 4A). At a PAR of 1000 μmol m$^{-2}$ s$^{-1}$, the CO$_2$ gross uptake of late snowmelt monoliths was 1.5 times...
higher under overcast conditions compared to sunny conditions (Fig. 4A), even though ambient air temperature was around 5 °C lower (Supplementary Information, Fig. S1).

For sunny and overcast conditions, the daily GPP values were linearly related to the LAI (Fig. 5). This may be explained by the strong relationship between LAI and net carbon uptake for a range of LAI (Fig. 5). For low LAI values, the daily GPP strongly increases with LAI, indicating that light capture is the main limiting factor of carbon uptake. Then, the slight decrease of GPP with LAI may be explained by a decrease in net assimilation due to a ‘dilution’ effect. The modelled GPP under cloudy skies was lowered by around 10% compared with cloudless skies, for example 6.5 against 7.3 g C m⁻² d⁻¹ for C180 canopies (Fig. 4). We found a negligible effect of leaf eccentricity (see Table 1) on this trade-off between light capture – driven by LAI – and CO₂ fixation – driven by N₄ mass (data not shown). Finally, it should be noted that for a given N₄ mass, alpine canopies operate at a higher LAI than the optimal LAI (Fig. 4).

A sensitivity analysis of the seasonal GPP model was conducted by estimating the effect of a 10% increase in a factor while keeping all other characteristics constant (Fig. 6A). The simulations were run for a 100-d period (see Material and Methods). A 10% increase in the length of growing season (corresponding to a shift of 10 d for the snowmelt) had the greatest impact on the seasonal GPP (Fig. 6A). By comparison, a shift to clear sky conditions throughout the season had a weaker effect. Similarly, increased temperature during the whole season did not compensate for 10 d lost in the growing season. LAI and two nitrogen-related factors, N₄ mass, and N₄ have a noticeable impact on GPP, but still lower than that of the length of growing season (Fig. 6A). The shift from a uniform to a linearly decreasing nitrogen distribution (pₛ = 1) also had a weaker effect on GPP, roughly similar to the effect of a temperature or an atmospheric CO₂ increase. Finally, a 10% change in relative humidity, leaf angle, or physiological parameters related to stomatal conductance changed the GPP by less than 1%.

The integrated values of GPP over the growing season were around 200 g C m⁻², except for the plant communities C140 and C150 (Fig. 6B). GPP simulations were also performed without the snow-induced shortening of the growing season. For the late-snowmelt sites, the model predicted a severe reduction in the carbon uptake because of the delayed snowmelt. However, the results indicated that the functional properties of these canopies (greater N₄ mass and LAI) largely compensated for this negative impact of a reduced growing season.

**DISCUSSION**

Our study emphasizes the interplay between short-term and long-term effects of snow-cover duration on the seasonal carbon uptake of alpine canopies. Short-term effects are driven by the direct influence of snow cover on the seasonal light and temperature regimes, whereas long-term effects correspond to the ecological sorting of species and plant traits along snow-cover gradients. A main result is that the snow-induced reduction in the carbon uptake period is counterbalanced by increased efficiency of carbon gain, which is made possible by the particular leaf trait combination of exploitative strategists that occur at the snowy sites. To our knowledge, this is the first attempt to determine the complex impact of snow on the seasonal GPP of temperate alpine canopies.

Instantaneous CO₂ flux measurements under different light conditions are predicted well by our canopy photosynthesis model. We are thus confident that the use of community-aggregated values of the chosen leaf traits is relevant to simulate the carbon uptake at the community level, as hypothesized in previous conceptual work (Diaz and Cabido, 2001). We found that the assimilation rate of the whole canopy (expressed per unit ground area) was of the same magnitude as the leaf assimilation rate (expressed per unit leaf area), which is consistent with other studies (Grabherr and Cernusca, 1977; Diemer, 1994; Tappeiner
and Cernusca, 1998). Compared with the most widely investigated temperate alpine community, i.e. *Carex curvula*-dominated alpine meadow (Diemer and Körner, 1998), the measured and modelled carbon uptake are higher for canopies of late-snowmelt sites and lower for early snowmelt sites.

Scaling-up from detailed plant physiological studies to ecosystem or regional scales requires taking into account variations in vegetation composition and community structure. Approaches based on *a priori* classification of plants into functional types have shown some limitations (Naeem and Wright, 2003; Reich *et al.*, 2004). Our study shows how integrating the trait-based approaches of comparative plant ecology with canopy-functioning models addresses this difficulty. However, recent findings suggest that functional diversity, i.e. the distribution and range of trait values in a given plant community, might be another key driver of ecosystem functioning (Naeem and Wright, 2003; Reich *et al.*, 2004). Clearly, a further challenge in ecosystem modeling would be to explicitly incorporate functional diversity effects into biogeochemical models.

**Fig. 3.** Relationships between community-aggregated values of (A) leaf nitrogen concentration on a mass basis (*N*<sub>mass</sub>) and mean leaf angle, and (B) leaf nitrogen content on an area basis (*N*<sub>area</sub>) and specific leaf area (SLA). Means (± s.e.) were calculated from 4–9 different plots (see Table 1). The numbers above the squares indicate the mean snowmelt date for each community in Julian days.

**Fig. 4.** Canopy gross CO<sub>2</sub> uptake for sunny and overcast conditions in mid-July 2006. Closed chamber measurements were performed (A) on monoliths dominated by *Carex foetida* sampled at a late-snowmelt site (C180), and (B) on monoliths dominated by *Kobresia myosuroides* sampled at an early snowmelt site (C140). The relationships between measured and predicted values are shown in the two insets. Evaluation of the model performance is as follows: (A) *n* = 50, *r*<sup>2</sup> = 0.89, RMSE = 0.033, MAE = 0.026; (B) *n* = 46, *r*<sup>2</sup> = 0.95, RMSE = 0.025, MAE = 0.021.
There are several possible shortcomings when simulating the GPP over the growing season. For example, we considered seasonal variations in incoming radiation and degree-days, excluding the potential impact of changes in soil water content on canopy assimilation. Our continuous measurements of gravimetric soil water content, at 5 cm below ground, did not show significant differences between early and late-snowmelt sites, and only a slight decrease through the growing season (F. Baptist, unpubl. res.). The soils of the study site are deep and the average rainfall between mid-May and mid-August for the three years, 2004–2006, was around 300 mm. These features should ensure enough water is available to plants in the conditions of low evaporative demand normal for high-elevation meadows (Körner, 1999). Moreover, we did not consider all the potential changes in plant functioning over the growing season. For example, the nitrogen content of late-snowmelt canopies is particularly high immediately after their release from snow cover, but then decreases slightly (F. Baptist, unpubl. res.). This may cause an over-estimation of the seasonal GPP at
late-snowmelt sites. These limitations call for further refi-
ments of the model and, as such, absolute values of the sea-
sonal GPP estimates should be considered with caution.
However, these limitations should not distort the con-
clusions about the relative impact of growing season length vs. canopy functional properties on carbon uptake
along the snowmelt gradient.

In our simulations, leaf geometrical properties did not
exert a strong influence on GPP. Canopy photosynthesis
models, based on the Monsi–Saeki theory, also show that
the assimilation rate of canopies with a LAI under 2.5
is largely independent of the extinction coefficient, $K$
(Hirose, 2005). However, our model neglects other poten-
tial effects of leaf inclination, for example the effect on
night-time frost and possible low-temperature photo-
inhibition (Germino and Smith, 2001). Presently, we do
not have enough empirical data to assess the relative
importance of such mechanisms at the canopy level and
over the growing season.

The results suggest that the alpine canopies do not
operate at their optimal LAI (Fig. 5). It is clear that
stand-level properties are not exclusively dependent upon
maximizing carbon uptake and that individuals are the
units under selection, not canopies (Hirose, 2005). Some
theoretical approaches have also highlighted that the
optimal LAI is not evolutionary stable if one takes into
account competition among individuals (Anten and
Hirose, 2001). Perhaps more interestingly, the comparison
of canopy functioning along the snowmelt gradient might
call for a more detailed investigation of the optimal LAI–
N relationships for different lengths of growing season.

As reported in other studies (De Pury and Farquhar,
1997; Gu et al., 2002), the sun–shade model allows a
more realistic treatment of the difference in the canopy
photosynthetic response to direct and diffuse radiation.
Increased carbon uptake under diffuse radiation has already been reported (Roderick et al., 2001). The
deep-shaded leaf fraction within vegetation canopies is
strongly reduced on cloudy days compared to cloudless
days as a result of the increased diffuse fraction of incoming
radiation. Furthermore, at noon there is a lower probability
that canopy photosynthetic saturation will occur under over-
cast conditions compared to sunny conditions (Gu et al.,
2002).

The results support the view that the traits of exploitative
strategists (especially the high leaf $N_{\text{mass}}$, the rapid growth
of photosynthetic organs) should permit the constraint of
a shortened carbon-uptake period to be overcome.
However, both conservative and exploitative strategies are
known to be adaptive under severe limitation of the
carbon uptake period (Kikuzawa and Kudo, 1995).
Obviously, the exploitative strategy is strongly dependent
upon sufficient soil nutrient availability. The late-snowmelt
sites that were investigated benefit from a pulse of inorganic
nitrogen at the time of snowmelt, as compared to
early snowmelt sites (F. Baptist, unpubl. res.; see
Supplementary Information online). These results are also
consistent with other comparisons along snowmelt gradi-
ents (Bowman et al., 1993; Fisk et al., 1998; Jaeger
et al., 1999). It is therefore likely that in the late-snowmelt
sites that were studied, this nutrient pulse at the onset of
growing season allowed a rapid expansion of photosynthetic
tissues, which ensured efficient light capture and carbon
fixation.

Conclusions

For cold ecosystems, the carbon-uptake period is primar-
ily determined by the snow-cover duration. Here, we have
demonstrated that the snow-induced changes in the length
of growing season had the highest impact on the seasonal
GPP. Our study is among the first ones to integrate the func-
tional trait approach with instantaneous measurements and
integrated estimates of ecosystem functioning. This
approach is particularly promising because continuous
recordings of CO₂ fluxes have been shown to be technically
difficult in alpine environments with strong bioclimatic
gradients.

Climatic change in will affect snow regimes in temperate
mountains (Keller et al., 2005; Euskirchen et al., 2006).
Increased temperature and reduced snow precipitation
may be responsible for earlier snowmelt. But the phenol-
gical responses of alpine species to a lengthening growing
season are still hard to predict (Starr et al., 2000; Wipf
et al., 2006; Bjork and Molau, 2007). One might predict
a small impact on carbon uptake if plant communities are
dominated by periodic species, i.e. species with a fixed,
genetically controlled growing period (Sorensen, 1941).
Conversely, the short-term consequences for ecosystem pro-
ductivity would be stronger if aperiodic species, i.e. species
able to extend their vegetative growth, are dominatant.
Future studies should address these issues for a better esti-
mate of seasonal GPP in alpine meadows in response to
global climate change.

SUPPLEMENTARY INFORMATION

Supplementary material is available online at http://aob.
oxfordjournals.org/ and consists of the following figures
and tables. Figure S1: the daily course of temperature, rela-
tive humidity and photosynthetically active radiation for
sunny, intermediate and cloudy days in May–August.
Figure S2: Relationship between the maximum rate of car-
boxylation ($V_{c,\text{max}}$) and the leaf nitrogen content per unit
area ($N_{\text{area}}$). Figure S3: daily uptake of nitrate and
ammonium by a resin bag inserted at 5 cm below ground
in the C140, C160 and C180 communities. Table S1: list
of constants, parameters and lumped variables used in the
model. Table S2: list of the main equations of the model.

ACKNOWLEDGEMENTS

The authors would like to acknowledge S. Aubert,
K. Charra-Vascou, C. Flahault and G. Girard, who assisted
in the field and the laboratory. We are indebted to
M. Robson and F. Quétier for discussions and comments
on an earlier version of this manuscript. Logistical
support was provided by the Station Alpine J. Fourier of
Grenoble. This work was supported by the University of
Grenoble and by the Centre National de la Recherche
Choler P. 2005.
